

Optimum Time Resource Allocation for TDMA-Based Differential Decode-and-Forward Cooperative Systems: A Capacity Perspective

Li Wang and Lajos Hanzo

Abstract—It is widely recognized that differential decode-and-forward (DDF) cooperative transmission schemes are capable of achieving a cooperative diversity gain, while circumventing the potentially excessive-complexity and yet inaccurate channel estimation, especially in mobile environments. In this letter, we find the optimum transmit-interval duration for the source and relay in the context of TDMA-based DDF-aided half-duplex systems for the sake of maximizing the achievable network throughput. We also demonstrate from a pure capacity perspective, in what scenarios the introduction of cooperation improves the achievable throughput.

Index Terms—Time resource allocation, TDMA, decode-and-forward relaying, cooperative system.

I. INTRODUCTION

USER-COOPERATION based transmit diversity techniques [1] constitute powerful arrangements of mitigating the deleterious effects of fading by creating a virtual antenna array from the single-antenna based shirt-pocket-size wireless devices. However, we have to circumvent the potentially excessive-complexity and yet inaccurate channel estimation in TDMA-based differential modulation assisted cooperative communications [2–4]. Hence, differentially encoded transmissions combined with non-coherent detection becomes an attractive design alternative. However, the majority of TDMA-based cooperative system optimization efforts has been focused on power allocation and relay station (RS) selection [1, 4, 5] based on a fixed and predetermined time resource allocation (TRA) between the source and RS. Recently, the TRA problem was investigated in [6] in order to maximize the so-called effective capacity in a two-source single-relay-aided system. In this letter, we deduce the optimum TRA policy for the sake of maximizing the DDF-aided cooperative system's capacity, by utilizing information theoretical tools. Furthermore, it is important to note that the cooperative diversity gain and the path-loss reduction induced power gain¹ are achieved by a half-duplex relay at the cost of suffering a significant throughput loss imposed by the relay's transmissions. Hence, in the interest of achieving a high spectral efficiency, we also identify the scenarios, when the introduction of cooperation becomes beneficial from a pure capacity perspective.

¹This is an explicit benefit of the reduced length of the relay-destination link with respect to the source-destination link.

Fig. 1. Single-relay-aided cooperative cellular uplink.

II. SYSTEM ARCHITECTURE & CHANNEL MODEL

The TDMA-based DDF cooperative cellular uplink (UL) considered is illustrated in Fig. 1, where a single cooperating mobile station (MS) is activated to forward the source MS's signal to the base station (BS). Each MS employs a single antenna, owing to their cost- and size-constraints. In order to avoid CSI estimation, both the source and RS employ conventional differential modulation schemes, such as DQPSK. Since our emphasis is on investigating the TRA, we stipulate the simplifying assumption of equal power allocation and mid-point RS location, as shown in Fig. 1.

In order to facilitate the non-coherent detection-based system capacity analysis, we consider a *time-selective block-fading* Rayleigh channel [7], where the fading coefficients exhibit correlation within a fading block according to the normalized Doppler frequency f_d induced by the relative movement of the transceivers, and changes in an i.i.d. manner from block to block.

The signals consecutively received within a fading block size of T_b at the RS during the broadcast Phase I, when a total of L_s symbols per transmission block are transmitted from the source MS, may be formulated as:

$$\mathbf{y}_r^I = \sqrt{P_s} \mathbf{S}_{D,s}^I \mathbf{h}_{sr} + \mathbf{w}_r, \quad (1)$$

where \mathbf{y}_r^I , \mathbf{h}_{sr} , and \mathbf{w}_r represent the received signal's column vector, the fading coefficients' column vector obeying a complex-valued Gaussian distribution $\mathcal{CN}(0, \sigma_{sr}^2)$ and the Gaussian noise column vector having a distribution of $\mathcal{CN}(0, 2\sigma_w^2)$, respectively. The diagonal matrix $\mathbf{S}_{D,s}^I$ may be expressed as $\mathbf{S}_{D,s}^I = \text{diag}\{s_s^I\}$, where s_s^I is the transmitted signal's column vector hosting the T_b symbols of a fading block during Phase I. Similarly, the block-wise signal model at the BS during Phases I and II can be expressed respectively as:

$$\mathbf{y}_d^I = \sqrt{P_s} \mathbf{S}_{D,s}^I \mathbf{h}_{sd} + \mathbf{w}_d, \quad (2)$$

and

$$\mathbf{y}_d^{II} = \sqrt{P_r} \mathbf{S}_{D,r}^{II} \mathbf{h}_{rd} + \mathbf{w}_d. \quad (3)$$

III. THE TRA-OPTIMIZED NETWORK CAPACITY

In this section the DDF-aided relay system's capacity will be discussed, followed by the derivation of the optimum TRA policy.

A. Decode-and-Forward Cooperative Network Capacity

Let us now consider the capacity of the DDF-aided cooperative system of Fig. 1. Based on the general upper and lower bounds on the capacity of half-duplex relay systems presented in [5] and on the fact that in our DDF-aided half-duplex relay system, the source MS remains silent during Phase II, when a total of L_r symbols are transmitted by the RS, we may obtain simplified capacity upper and lower bounds for the DDF system of Fig. 1 as:

$$C_{coop}(\gamma_e^o, \alpha) \leq \min\{\alpha I(\mathbf{s}_s^I; \mathbf{y}_d^I, \mathbf{y}_r^I), \\ \alpha I(\mathbf{s}_s^I; \mathbf{y}_d^I) + (1 - \alpha)I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II})\}, \quad (4)$$

and

$$C_{coop}(\gamma_e^o, \alpha) \geq \min\{\alpha I(\mathbf{s}_s^I; \mathbf{y}_r^I), \\ \alpha I(\mathbf{s}_s^I; \mathbf{y}_d^I) + (1 - \alpha)I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II})\}, \quad (5)$$

where $I(\mathbf{a}; \mathbf{b})$ represents the *average* mutual information (MI) between the channel input \mathbf{a} and the corresponding channel output \mathbf{b} , while the TRA-factor α is defined as:

$$\alpha \triangleq \frac{L_s}{L_s + L_r} = \frac{R_r}{R_s + R_r}, \quad (6)$$

since the ratio of the time durations (L_s, L_r) used by the source and RS is inversely proportional to the ratio of the channel code rates (R_s, R_r) employed by them². Note that the capacity upper and lower bounds of (4) and (5) are functions of the network's overall equivalent SNR³, i.e. γ_e^o and the TRA-factor α of (6).

On the other hand, given a fading block size T_b and a M_c -ary DPSK scheme, the actual transmission rate, R_{coop} , of the cooperative system of Fig. 1 is a function of both R_s and α , which may be expressed as $R_{coop}(R_s, \alpha) = \alpha R_s \frac{T_b - 1}{T_b} \log_2 M_c$, where the ratio of $\frac{T_b - 1}{T_b}$ accounts for the modest rate-loss induced by the known reference symbol of the classic differential signalling process. Furthermore, in order for the RS to decode the received signal correctly thus avoiding the potential error propagation, the source transmission rate should be below the non-coherent constrained information rate of the source-relay link, thus we have:

$$R_{coop}(R_s, \alpha) \leq \alpha C_{sr}(\gamma_e^o) = \alpha I(\mathbf{s}_s^I; \mathbf{y}_r^I). \quad (7)$$

Consequently, according to (4), (5) and (7), the DDF-aided cooperative network capacity⁴ can be written as:

$$C_{coop}^{DDF}(\gamma_e^o, \alpha) \\ = \min\{\alpha I(\mathbf{s}_s^I; \mathbf{y}_r^I), \alpha I(\mathbf{s}_s^I; \mathbf{y}_d^I) + (1 - \alpha)I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II})\}, \quad (8)$$

indicating that the TRA-factor α of (6) plays a crucial role in determining the network's capacity. The constrained information rates of $I(\mathbf{s}_s^I; \mathbf{y}_d^I)$, $I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II})$ and $I(\mathbf{s}_s^I; \mathbf{y}_r^I)$ can be

²The flexibility of code-rate-allocation may be ensured by rateless codes, for example.

³The terminology of 'equivalent SNR' is used here to indicate the fact that it quantifies the ratio of the transmit power and the receiver's noise, which are measured at physically different points. γ_e^o denotes the network's overall equivalent SNR, having the following relationship with the equivalent SNRs, γ_e^s and γ_e^r at the source and relay transmitters: $\gamma_e^s + \gamma_e^r = \gamma_e^o = P/2\sigma_w^2$.

⁴It is defined as the maximum achievable rate of the relaying system for the employment of the DDF scheme, where the relay would not forward the signal received from the source if it is unable to decode it correctly.

evaluated using the method presented in [7].

B. Optimum Time Resource Allocation for the DDF System

Lemma 1: The optimum TRA-factor $\hat{\alpha}^{opt}$, which maximizes the achievable information rate of a single-relay-aided DDF-based cooperative transmission, is given by:

$$\hat{\alpha}^{opt}(\gamma_e^o) = \frac{I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II})}{I(\mathbf{s}_s^I; \mathbf{y}_r^I) - I(\mathbf{s}_s^I; \mathbf{y}_d^I) + I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II})}, \quad (9)$$

yielding the globally maximum achievable rate of

$$C_{coop}^{DDF}(\gamma_e^o, \hat{\alpha}^{opt}) = \frac{I(\mathbf{s}_s^I; \mathbf{y}_r^I)I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II})}{I(\mathbf{s}_s^I; \mathbf{y}_r^I) - I(\mathbf{s}_s^I; \mathbf{y}_d^I) + I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II})}. \quad (10)$$

Proof of Lemma 1: For a given γ_e^o , we can find $\alpha = a$, which satisfies $aI(\mathbf{s}_s^I; \mathbf{y}_d^I) + (1 - a)I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II}) = aI(\mathbf{s}_s^I; \mathbf{y}_r^I)$, hence the resultant network capacity of (8) becomes:

$$C_{coop}^{DDF}(\gamma_e^o, a) = aI(\mathbf{s}_s^I; \mathbf{y}_d^I) + (1 - a)I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II}) \\ = aI(\mathbf{s}_s^I; \mathbf{y}_r^I). \quad (11)$$

Furthermore, due to the path-loss reduction induced power gain, which implies that we have $\sigma_{h_{sd}}^2 < \sigma_{h_{rd}}^2$, and owing to the equal power allocation assumption, i.e. $P_s = P_r$, it is evident that

$$I(\mathbf{s}_s^I; \mathbf{y}_d^I) < I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II}). \quad (12)$$

Thus, for any $\alpha = b > a$, we have:

$$bI(\mathbf{s}_s^I; \mathbf{y}_d^I) + (1 - b)I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II}) < aI(\mathbf{s}_s^I; \mathbf{y}_d^I) + (1 - a)I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II}), \quad (13)$$

which in turn results in

$$bI(\mathbf{s}_s^I; \mathbf{y}_d^I) + (1 - b)I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II}) < aI(\mathbf{s}_s^I; \mathbf{y}_r^I) < bI(\mathbf{s}_s^I; \mathbf{y}_r^I). \quad (14)$$

Hence, according to (8), the network capacity associated with $\alpha = b$ may be expressed as:

$$C_{coop}^{DDF}(\gamma_e^o, b) = bI(\mathbf{s}_s^I; \mathbf{y}_d^I) + (1 - b)I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II}). \quad (15)$$

Based on (11), (13) and (15), we arrive at:

$$C_{coop}^{DDF}(\gamma_e^o, b) < C_{coop}^{DDF}(\gamma_e^o, a), \quad \text{if } b > a. \quad (16)$$

On the other hand, according to (11) and (12), for any $\alpha = c < a$, we have:

$$cI(\mathbf{s}_s^I; \mathbf{y}_d^I) + (1 - c)I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II}) \\ > aI(\mathbf{s}_s^I; \mathbf{y}_d^I) + (1 - a)I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II}) = aI(\mathbf{s}_s^I; \mathbf{y}_r^I). \quad (17)$$

Additionally, since $c < a$, we have:

$$cI(\mathbf{s}_s^I; \mathbf{y}_r^I) < aI(\mathbf{s}_s^I; \mathbf{y}_r^I), \quad (18)$$

which in turn yields $cI(\mathbf{s}_s^I; \mathbf{y}_d^I) + (1 - c)I(\mathbf{s}_r^{II}; \mathbf{y}_d^{II}) > cI(\mathbf{s}_s^I; \mathbf{y}_r^I)$. Again, according to (8), the maximum achievable information rate associated with $\alpha = c$ may be formulated as:

$$C_{coop}^{DDF}(\gamma_e^o, c) = cI(\mathbf{s}_s^I; \mathbf{y}_r^I). \quad (19)$$

Consequently, by referring to (11), (18) and (19), it becomes plausible that:

$$C_{coop}^{DDF}(\gamma_e^o, c) < C_{coop}^{DDF}(\gamma_e^o, a), \quad \text{if } c < a. \quad (20)$$

Fig. 2. Capacity of the single-relay-aided DDF cooperative system.

Hence, based on (16) and (20), the optimum TRA-factor that maximizes the achievable network information rate is $\alpha^{opt} = a$, which can be computed with the aid of (11). Finally, after some straightforward mathematical manipulations, we arrive at (9), which in turn leads to the globally maximum achievable network information rate of (10). This completes the proof of Lemma 1.

Remarks: Although the optimum TRA solution of (9) is derived under the assumption of equal power allocation and mid-point relay location, we emphasize that it remains valid, as long as (12) holds. Furthermore, for the optimum power allocation and relay selection scheme of [4], (12) holds with a high probability, especially when the path-loss exponent v is high. On the other hand, it is also important to note that the optimum TRA solution of (9) is generally applicable to relay-aided systems, regardless whether coherent or non-coherent techniques are used.

IV. NUMERICAL EVALUATION AND DISCUSSIONS

In Fig. 2 the single-relay-aided cooperative system's capacity associated with different values of α is depicted versus γ_e^o using (8) in comparison to that of its adaptive-TRA-aided counterpart in conjunction with the optimum α of (9) in a typical urban cellular radio scenario associated with the path loss exponent of $v = 3$. It is observed that the latter exhibits significant capacity gains over the former with the aid of the adaptive TRA scheme. Importantly, as γ_e^o increases, the increasing optimal value of α indicates that more time resources should be allocated to the source.

In order to gain further insights into the benefits of the single-relay-assisted DDF cooperative system over its conventional direct-transmission based counterpart from a pure capacity perspective, the capacity of the adaptive-TRA-aided cooperative system is depicted in comparison to that of the direct-transmission based one in Fig. 3. It may be observed in the figure that when the overall equivalent SNR is relatively low, the TRA-optimized DDF cooperative system exhibits a significantly higher capacity than its direct-transmission based

Fig. 3. Capacity comparison of the single-relay-aided cooperative system and its direct-transmission based counterpart.

counterpart in typical urban cellular radio scenarios. More specifically, in a shadowed urban area associated with $v = 4$, the DDF system only requires one third of the total transmit power necessitated by its direct-transmission based counterpart in order to achieve a spectral efficiency of 0.5 bits/s/Hz. However, the achievable capacity gain may be substantially reduced, if we encounter a free-space propagation scenario associated with $v = 2$, since the path-loss reduction induced power-gain achieved is insufficiently high to compensate for the significant multiplexing loss inherent in the single-relay-aided half-duplex TDMA system. Moreover, as the overall equivalent SNR increases to a relatively high value, the benefits of invoking a single-relay-aided cooperative system for achieving a high spectral efficiency erode.

V. CONCLUSION

In this letter, we proposed an optimum TRA scheme for the DDF cooperative system, which was shown to be capable of maximizing the network's capacity.
